Lab 7: Estimating Causal Effects via Instrumental Variables

Welcome to the seventh DS102 lab!

The goals of this lab is to implement and get better understanding of Instrumental Variables discussed in Lecture. Along with Inverse Propensity Scaling which you will see in Lecture, Instrumental Variables are often used to determine causal effects.

The code you need to write is commented out with a message "TODO: fill in".

Collaboration Policy

Data science is a collaborative activity. While you may talk with others about the labs, we ask that you write your solutions individually. If you do discuss the assignments with others please include their names in the cell below.

Gradescope Submission

To submit this assignment, rerun the notebook from scratch (by selecting Kernel > Restart & Run all), and then print as a pdf (File > download as > pdf) and submit it to Gradescope.

This assignment should be completed and submitted before Wednesday, October 27, 2021 at 11:59 PM. PST

Collaborators

Write the names of your collaborators in this cell.

<Collaborator Name> <Collaborator e-mail>

```
import matplotlib.pyplot as plt
import numpy as np
import pandas as pd
import statsmodels.api as sm
import seaborn as sns
import itertools
from ipywidgets import interact, interactive

import hashlib

sns.set(style="dark")
plt.style.use("ggplot")
%matplotlib inline
```

Instrumental Variables Background

Suppose that we measure Z, the number of books a student read in the last year, and we are intrested in determing how Z affects an observed target outcome Y, the student's SAT score. The effect we are interested

in is **causal** because we want to know how Y changes if all randomness other than Z remains fixed, and only Z changes. We will refer to Z as the "treatment". In general, Z might be multi-dimensional, however for the purpose of this exercise we take $Z \in \mathbb{R}$.

Suppose there's also a confounder X, which is the income of the student's family. We don't observe X, but it affects both the number of books the student reads (wealthier families may have more access to books) and the student's SAT score (wealthier students may have more access to SAT tutoring).

We assume that the outcome is generated as a linear function of the confounder X and treatment Z, with additive noise ϵ :

$$Y = \beta_1 Z + \beta_2 X + \epsilon$$

The goal is to estimate β_1 , the true causal effect of the number of books a student reads on their SAT score.

Danger of bias

As we saw in the instrumental variable lecture note (link here), if the confounder X is highly correlated with Z, performing ordinary least squares (OLS) on the observed data Z, Y can lead to very biased results.

Instrumental variables (IVs) and two-stage least squares (2SLS)

One way to get around this issue is by using **instrumental variables (IVs)**. A valid instrument W is a variable which is independent of the confounder X, and affects Y only through Z. For example, we can create such an instrument W by employing *encouragement design*, where we randomly assign students to "readathons" of different durations. See the figure below for a causal diagram:

Using the instrumental variable W, we can estimate β_1 by first "guessing" Z from W using ordinary least squares (OLS) (denoted \hat{Z}), and then regressing Y onto \hat{Z} (instead of Z) using OLS as well. This procedure is known as **two-stage least squares (2SLS)**.

In this lab, we will observe the bias that can occur when naively performing OLS on the observed data Z, Y, and also how employing 2SLS can achieve a better estimate of β_1 .

Model setup

Suppose that we have historical data from n=10,000 different students. Suppose we observe the following variables:

 $Z^{(i)}=\mbox{number of books the student read in the last year,}$

 $W^{(i)}=$ duration of the "readathon" at the student's school. Note: This is sligtly different from the setup in Discussion 7 where it was a binary variable

 $Y^{(i)}=$ the student's SAT score.

Suppose that the student's family income $X^{(i)}$ affects both $Z^{(i)}$ and $Y^{(i)}$, but is **not observed**.

Data Generation

The student's SAT score is linear in the number of books the student read and the student's family income:

$$Y^{(i)} = \beta_1 Z^{(i)} + \beta_2 X^{(i)} + \epsilon^{(i)}.$$

The number of books a student reads is linear in whether or not there was a readathon and the student's family income:

$$Z^{(i)} = \gamma_1 W^{(i)} + \gamma_2 X^{(i)} + \epsilon'^{(i)},$$

The true model was generated in the following manner:

- ullet Sample $W^{(i)} \sim N(20,5) \ \longleftarrow \$ Duration of Readathon for student i
- Sample $X^{(i)} \sim \text{Normal}(50, 10) \leftarrow$ Income in tens of thousands (10,000) dollars for the family of student i (unobserved variable)
- Generate $Y^{(i)}$ by setting $\beta_1=5$, $\beta_2=12$ and sampling a noise $\epsilon^{(i)}\sim N(0,10)$ \longleftarrow SAT score for student i.

Note: The data in this lab are not observed in real life. They are instead synthetic data generated according to the procedure described above.

Load the data

Run the cells below to load and plot the data.

```
In []: # Do not modify: Just run this to load the data
    student_data = pd.read_csv("SAT_data.csv")
    student_data.head()

In []: # make a pairplot illustrating the pairwise correlations between different columns in the
    fig = sns.pairplot(student_data, plot_kws=dict(marker="o", alpha = 0.5))
    for i, j in zip(*np.triu_indices_from(fig.axes, 1)):
        fig.axes[i, j].set_visible(False)
    plt.show()
```

In the plot above on the main diagonal we have the histograms of each variable, and on the off-diagonals we have scatter plots illustrating the corelations between pair of variables.

Question 1: Understanding the Model

1.a Correlations between variables

i) Just by inspecting the pairplot above rank in order from most correlated to least correlated the following pairwise relationships: Z & X, Z & Y, Z & W, X & Y, X & W, Y & W

TODO: X & Y, Z & Y, Z & X, Z & W, Y & W, X & W

ii) Which of the above pairs appear to be independent?

TODO: X & W

1.b Understanding the marginal impacts

Inspect the Data Generation section above, and answer the following questions.

- i) What is the true causal effect of an extra book read on the SAT score (i.e. if you hold everything else constant and you read one more book by how much will the SAT score change)?
- ii) What is the true causal effect of increasing income by 10000 on the SAT score?
- iii) What is the true causal effect of an extra readathon day on the number of books read?
- iv) What is the true causal effect of increaing income by 10000 on the number of books read?

i) **TODO**: 5

ii) **TODO**: 12

iii) TODO: 1

iv) TODO: 1

Ordinary Least Squares

If we had access to income data X, then we could estimate directely β_1 , β_2 , γ_1 , γ_2 from the data by setting up a linear regression problem and finding Ordinary Least Squares estimator.

$$\hat{eta}_1,\hat{eta}_2=rg\min_{eta_1,eta_2}\|Y-eta_1Z-eta_2X\|_2^2$$

$$\hat{\gamma}_1,\hat{\gamma}_2=rg\min_{\gamma_1,\gamma_2}\|Z-\gamma_1W-\gamma_2X\|_2^2$$

To find OLS estimators we will use sm.OLS from statsmodels.api.

```
In [ ]:
         # No TODOs here: Just examine the code
         def fit_OLS_model(df, target_variable, explanatory_variables, intercept = False):
             Fits an OLS model from data.
             Inputs:
                 df: pandas DataFrame
                 target_variable: string, name of the target variable
                 explanatory_variables: list of strings, names of the explanatory variables
                 intercept: bool, if True add intercept term
             Outputs:
                 fitted_model: model containing OLS regression results
             target = df[target_variable]
             inputs = df[explanatory_variables]
             if intercept:
                 inputs = sm.add_constant(inputs)
             fitted_model = sm.OLS(target, inputs).fit()
             return(fitted_model)
```

```
gammas_model = fit_OLS_model(student_data, 'NumBooks', ['ReadathonDuration', 'Income'])
print(gammas_model.summary())

In []:  # Print the fitted_estimators
gammas = gammas_model.params
print("The estimated causal effect on number of books read of an additional Readathon day
print("The estimated causal effect on number of books read of an additional $10000 is {:...2
# The numbers you get should be very close to you answer in 1.b
```

1.c Estimate causal effect of NumBooks and Income on the SAT Score

Fill in the code below (similar as above) to estimate the causal effect of NumBooks and Income on the SAT Scores.

```
In [14]: # Compute OLS estimators for beta_1 and beta_2
betas_model = fit_OLS_model(student_data, 'SAT',['NumBooks','Income'])
print(betas_model.summary())
```

```
OLS Regression Results

```

Test passed!

In Question 1 we saw how we can estimate all causal relationships if we have access to the income variable. However in our actual data we **do not observe Income**.

Goal: estimate β_1 , the true causal effect of the number of books a student reads on their SAT score without access to the Income variable.

2. Naive OLS: OLS on the observed variables Z, Y.

The confounding variable X (family income) is unfortunately unobserved. We will start by somewhat "naively" attempting to estimate the causal effect β_1 by using plain linear regression (OLS) on the observed variables Z and Y. This time we will include an intercept term:

$$\hat{\beta}_1, \hat{c} = \arg\min_{\beta_1, c} \|Y - \beta_1 Z - c\|_2^2$$

2.a. Fit Naive OLS

```
In [19]:
```

```
# TODO: Fit OLS parameters to predict Y from Z.
beta_naive_model =fit_OLS_model(student_data, 'SAT', 'NumBooks', intercept=True)
print(beta_naive_model.summary())
```

```

The Naive OLS estimate of beta_1 is 12.96, while the true beta_1 is 5

2.b Does the Naive approach overestimate or under estimate the value of reading books?

Answer this question by comparing the naive estimate and the true value of β_1

TODO: : It is an overestimate because The Naive OLS estimate of beta_1 is 12.96, while the true beta_1 is 5

3. Instrumental variables and 2SLS

To eliminate the bias, we turn to instrumental variables. In the first stage, we "predict" the number of books a student read from whether or not they had a readathon, W, producing an estimate \hat{Z} . Then, in the second stage, we regress the SAT score Y onto the predicted number of books read \hat{Z} .

Stage 1: Predict treatment variable \hat{Z} from instrumental variable W

3.a Predict \hat{Z}

3.a.i Complete the code below to fit an OLS model that predicts \hat{Z} (estimated number of books read) using W (whether they had a readathon).

$$\hat{\gamma}_1,\hat{c} = rg\min_{\gamma_1,c} \|Z-\gamma_1W-c\|_2^2$$

```
In [23]: # TODO: Fit OLS parameters to predict Z from W
```
